Magnetic resonance imaging (MRI) is a medical imaging technique used in radiology and neurology to produce non-invasive images with superior soft tissue contrast. Radio-frequency (RF) fields are used to manipulate the spins of atoms within a subject's body, causing them to precess or rotate. Precession of the spins produces detectable magnetic field signals that are characteristic of the nucleus, or type of atoms, present. In MRI, such magnetic field signals are detected by one or more coils called antennas. Coil elements may be positioned within an MRI machine to generate an RF field that has sufficient strength to flip a desired number of atomic spins. This can be accomplished by superimposing a uniform magnetic field having a selected strength over the region of interest of the subject. The uniform magnetic field can be generated by a pair of Helmholtz coils, for example. Current techniques and systems for controlling field current in the Helmholtz coils and the like have used techniques to sense input voltage from a sensor coupled to a current sensing resistor. Such techniques are called “wet sense” techniques because the sensor is directly exposed to the current-carrying paths of the coils. When it comes to protecting sensitive areas in the magnet from getting wet (for example for patient safety), it is desirable that

the sensing resistor be made as small as possible because an increase in the voltage drop across the resistor causes the potential heat rise (Q) to increase. The amount of heat dissipated as a result of
